Paracoccidioidomycosis case series with and without central nervous system involvement

Vinicius Sousa Pietra Pedroso[1], Ana Claudia Lyon[1], Stanley Almeida Araújo[1], Juliana Márcia Ribeiro Veloso[1], Enio Roberto Pietra Pedroso[1,2] and Antônio Lucio Teixeira[1,2]

INTRODUCTION

Paracoccidioidomycosis (PCM), a systemic infection caused by the fungus Paracoccidioides brasiliensis (Pb), is the most important deep mycosis in South America[1]. It can be considered a public health problem due to the elevated social and economic costs borne not only by the active disease, but also by the frequent associated sequelae[2].

It affects patients of all ages, but is more common among individuals with ages ranging from 30 to 50 years. There are no differences in incidence between genders until puberty; however, in adult life, it becomes more frequent among men, in an 11:1 ratio[3].

The infection occurs by the inhalation of propagules of the fungus, resulting in a primary pulmonary complex, usually asymptomatic, which tends to resolve spontaneously, leaving residual lesions that may contain viable fungi for years. Nevertheless, in some cases, the primary infection develops, leading to a symptomatic pulmonary disease or spreading to other sites by hematological and/or lymphatic routes, affecting virtually any organ[3,4]. In general, the most affected sites are the lungs, the skin, mucous membranes, lymph nodes and adrenal glands. In the last decades, with the development of new diagnostic methods, especially neuroimaging, it was verified that central nervous system (CNS) involvement is much more common than was thought to be, taking place in approximately 12.5% of the cases[5,6] and reaching, in one study, 36% of them[7].

Several authors have associated the neurological form of PCM with prolonged clinical course, diffuse involvement and immunosuppression. However, a few works in the literature make comparisons between patients presenting NPCM and patients without neurological involvement. Most of these studies make only diagnostic comparisons between patients presenting NPCM and patients without neurological involvement. However, a few works in the literature make

METHODS

From October 1976 to August 2008, 213 PCM cases were assisted at the ambulatory. Epidemiological, clinical, laboratory, therapeutic and follow-up data were registered in a database generated by the software SPSS 12.0. The analyses were made with this software using the Chi-square, the Fisher exact tests or Student’s t-test.

Nine of the 213 cases presented neurological symptoms associated with the disease. However, one of these cases was excluded because the patient missed the follow-up and it was not possible to confirm...
the presence of CNS lesions. The diagnosis of NPCM was made by the presence of typical neuroimaging findings (ring-like contrast enhancement lesions - Figure 1) concomitantly with fungus isolation from other sites (lungs or skin). In three cases, diagnosis was further confirmed with neurosurgical drainage of brain lesions and fungus isolation.

**FIGURE 1** - Computed tomographic scan showing the typical ring-like appearance of a lesion located in the right thalamus (case 2).

**Ethical considerations**

This study was approved by the **Universidade Federal de Minas Gerais** Ethics Committee for Clinical Research.

**RESULTS**

The prevalence of NPCM among the observed population was 3.8% (95% confidence interval: 1.7-7.0). Seven patients were male, with mean age of 42 years, ranging from 24 to 61 years. One patient presented the subacute form of PCM and the other seven presented the chronic form of the disease, but all of them exhibited the parenchymatous form of NPCM.

Four patients were rural workers, two were bricklayers, one was a homemaker and there was no occupational information in one case.

Six patients had previous histories of non-neurological PCM and the other two patients had their PCM diagnosis made with the neurological manifestations. The disease was never limited to the CNS and the skin was the most frequently affected site (62.5%), followed by the lungs and lymph nodes (37.5%), and by mucous membranes (25%). Laryngeal and adrenal involvements were also observed. All the cases are summarized in Table 1.

The clinical picture was characterized especially by signs of intracranial hypertension (62.5% of the cases), and headache was the most common complaint. Motor deficits were observed in 44.4% of the cases; seizures, sensitive and cognitive deficits were exhibited by 33.3% of them.

NPCM’s mean time to diagnosis, defined as the period between the onset of neurological symptoms until the search for medical attention, was 3.8 months, ranging from one week to one year.

All patients underwent computadorized tomography scanning of the skull. Seventy-five percent of the lesions were located at the supratentorial compartment, while 50% were infratentorial. In the supratentorial compartment, the frontal lobes were the most affected sites, with 37.5% of the lesions, followed by the temporal and parietal lobes (25% each) and by the occipital lobes, basal nuclei and thalamus (12.5% each). In the infratentorial compartment, lesions were restricted to the cerebellum.

All patients were treated with more than one drug and the most used combination was amphotericin B with sulphamethoxazole-trimethoprim (n = 6). The azolic agents were commonly used too, especially Ketoconazole (n = 4). The mean treatment time was 4.5 years and there were no deaths. Surgical procedures (craniotomy with abscess drainage) were performed in three cases.

Approximately 63% of the patients developed sequelae in the follow-up: 60% of them remained with sensitive deficits, 40% of them, with motor deficits or seizures and 20% with gait disturbances.

After the characterization of the cases, data from NPCM patients were compared to non-neurological PCM patients.

Demographic profiles from both groups of patients were compared. No statistical difference was observed in gender distribution or age. When considering origin, it was observed that there were 42 PCM patients who came from the same Minas Gerais state’s macro regions from which NPCM patients came. This distribution was statistically different in the north/northeast region (60% of the patients who proceeded from this region (n=5) developed NPCM (n=3), p<0.001, Fisher exact test). There was also a difference in relation to the cases which came from other Brazilian States (Bahia, Espirito Santo and Pernambuco (24 PCM cases and 3 NPCM cases), p=0.042, Fisher exact test). The two groups had similar occupational distributions.

Clinical aspects were also compared. The mean time course of the disease was 11.4 months among NPCM patients and 13.83 months among PCM patients, without statistical difference. There were no differences related to the diagnosis form either.

Many clinical signals and symptoms exhibited by the patients at the first consultation were registered in the research protocol form. A positive association was observed between the neurological form of the disease and the presence of headache (p=0.001), sweating (p=0.004), seizures (p=0.006), dizziness (p=0.028) and focal deficit (p=0.011).

The frequency of non-neurological affected sites was also compared between the two groups. There was no difference among all the various forms of the disease and the development of NPCM, including the multifocal or disseminated form.

No differences were observed when considering the patients past medical history, intravenous drug use and previous or current tobacco use or alcoholism. However, there was a positive relation between PCM family history and the development of NPCM (p=0.014).

Finally, no differences related to the relapse of the disease or to the period passed until the relapse could be observed.

M: male; F: female; CT: computadorized tomography; SMT-TMP: sulphamethoxazole-trimethoprim.

This is in accordance with the growing trend of NPCM diagnosing in the last decades, which could be due to the expansion of modern neuroimaging methods. The majority of NPCM patients presented the chronic form of PCM, which is in accordance with the literature. Moreover, all the cases reported exhibited the parenchymatous form, mainly supratentorial. In a recent systematic review, we found that about 98.3% of NPCM cases corresponded to the chronic form of PCM, with 89.4% of the cases exhibiting the pseudotumoral or parenchymatous form of NPCM. Approximately 66.8% of the lesions occurred in the supratentorial compartment, particularly in the frontal and parietal lobes.

Despite the lack of deaths among the cases, morbidity was high. Nearly 63% of the patients developed some sequel. Furthermore, in patients who did not remain with any sequel, the time course of the neurological disease was never superior to 20 days. Otherwise, amongst patients who did develop sequelae, this period was longer. Hence, this observation alerts to the fact that with early diagnosis and treatment, the morbidity of the disease could be significantly reduced.
Epidemiological aspects evaluated between groups of patients with NPCM and PCM did not differ in relation with gender, age or occupational distribution, and these were all in accordance with the literature. There were no differences related to life habits such as the use of intravenous drug, tobacco or alcohol. Nonetheless, there was a significant difference (p<0.001) associated to the frequency of NPCM cases in patients proceeding from state’s of Minas Gerais North/ Northeast region and other states. This finding could simply reflect a bias related to the lack of referral neurology centers in those regions, leading the patients to be referred to the capital. However, it might be interesting to speculate on other possibilities. As a matter-of-fact, 60% of the cases originated from Minas Gerais’ North/Northeast region corresponded to NPCM cases. This region is geographically close to the States of Bahia and Espírito Santo, from where proceeded other two cases. In spite of the small number of patients observed and the limitations of this study, this observation could raise the hypothesis of the presence of different Pb strains or even Paracoccidioides species in this region which could be more prone to invade the CNS. In fact, there is a trend in the literature to define new Paracoccidioides species, with diverse geographical distributions and possibly different pathogenic patterns.

The analysis of the clinical manifestations showed the obvious but remarkable importance of neurologic signs in the assessment of NPCM patients, especially the presence of headache, seizures and focal deficits. The observation of these complaints in PCM patients should readily evoke the possibility of neurological involvement and neuroimaging methods are important in identifying CNS lesions.

It must be noted that the antifungal therapy most frequently used in our sample was Sulphamethoxazole-Trimethoprim and amphotericin B, the two drugs of choice in the treatment of NPCM. Furthermore, imidazole derivatives were commonly used, especially Ketoconazole (n=4). It should be noted that, with the exception of Fluconazole, these drugs have limited penetration in the CNS and questionable usage in NPCM. However, despite this, we observed in a systematic review of the literature that imidazole derivatives are frequently used in the treatment of NPCM, and Ketoconazole, Fluconazole and Itraconazole were used in 8.3%, 8.3% and 3.9% of the cases, respectively. This could be due to issues of cost and easy access.

Another interesting fact is the association between NPCM and a positive family PCM history. Despite the small number of patients and the resulting statistical limitations, it is worthy of note that we describe the involvement of a mother and her son (cases 1 and 2). The literature reports other cases of NPCM affecting relatives. Some genetic susceptibility factors to PCM development have been described, such as the HLA-A9 (related to a unifocal pulmonary chronic form), HLA-B13 and HLA-B40. Nevertheless, these associations were not observed among NPCM patients. Thus, susceptibility mechanisms which lead to CNS infection should depend on the interaction between fungal and host’s factors determining the parasite’s penetration into the nervous tissue.

Importantly, there were no significant differences related to disease time course between patients with or without neurological infection. This fact suggests that there is not an association between CNS involvement and a longer course of the systemic disease. There were no noticeable differences also regarding the involvement of non-neurological sites between PCM and NPCM patients. In contrast with some works in the literature, there were no differences even in regard to the multifocal form of the disease. As mentioned, it has been suggested that the penetration of the fungus in the CNS could be related with some specific clinical aspects, particularly severe immunosuppression and intense disease dissemination. However, this was not confirmed in our sample. Thus, our data show that the neurological form was not related to dissemination or to a longer course of disease, and that there could be other factors than simply immunosuppression that could be involved in CNS infection, as specific parasite’s or host’s characteristics.

To conclude, the demographic and clinical data of the eight NPCM cases reported are similar to those generally attributed to this form of the disease by the literature. Early diagnosis and treatment showed to be fundamental. In comparison to patients without CNS involvement, it could be observed the great importance of neurological examination and neuroimaging. The development of NPCM was not related to prolonged disease course or dissemination and the differences regarding family history and origin, even with limitations, could point to the need of further studies in order to determine susceptibility factors involved in the neurological infection.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest.

ABSTRACT IN PORTUGUESE

Série de casos de paracoccidioidomicose com e sem envolvimento do sistema nervoso central

Introdução: A paracoccidioidomicose (PCM) é uma micose profunda mais importante na América do Sul. O comprometimento do sistema nervoso central é grave e pode ocorrer em 12,5% dos casos. Este trabalho tem como objetivo descrever oito casos de neuroparacoccidioidomicose (NPCM) e comparar suas características com pacientes sem envolvimento neurológico, a fim de identificar aspectos singulares da NPCM. Métodos: Uma coorte de 213 casos de PCM foi avaliada na Clínica de Doenças Infecciosas do Hospital das Clínicas da Universidade Federal de Minas Gerais, de outubro de 1976 a agosto de 2008. Dados epidemiológicos, clínicos, laboratoriais, terapêuticos e de seguimento foram registrados. Resultados: Oito pacientes apresentaram NPCM. A prevalência de NPCM observada foi de 3,8%. Um paciente apresentou a forma subaguda da PCM e sete apresentaram a forma crônica. Todos os pacientes apresentaram a forma parenquimatosa. Cerca de 60% dos pacientes provenientes das regiões norte e nordeste de Minas Gerais desenvolveram NPCM. Foi observado o desenvolvimento de NPCM em uma mãe e em seu filho. Os pacientes com NPCM apresentaram perfis demográficos e clínicos similares à descrição da literatura. Quando comparados aos pacientes com PCM, houve diferenças em relação à procedência de tais pacientes e história familiar positiva de PCM. Conclusões: Os resultados confirmam a importância da avaliação neurológica em pacientes com PCM. Apesar das limitações desse trabalho, as diferenças com relação à procedência dos pacientes e à história familiar apontam para a necessidade de mais estudos para investigar a existência de fatores de susceptibilidade envolvidos no desenvolvimento da NPCM.
