**Highlights**
- Vibrational spectroscopy enables subtle details of the molecular structure of whiteite.
- Crystals of a pure phase from a Brazilian pegmatite were used.
- Raman and infrared bands are assigned to the vibrations of PO\(_4\)\(^3-\).
- A comparison is made with the vibrational spectra of wardite.

**Abstract**
Vibrational spectroscopy enables subtle details of the molecular structure of whiteite to be determined. Single crystals of a pure phase from a Brazilian pegmatite were used. The infrared and Raman spectroscopy were applied to compare the molecular structure of whiteite with that of other phosphate minerals. The Raman spectrum of whiteite shows an intense band at 972 cm\(^{-1}\) assigned to the \(\nu_1\) PO\(_4\)\(^3-\) symmetric stretching vibrations. The low intensity Raman bands at 1076 and 1173 cm\(^{-1}\) are assigned to the \(\nu_3\) PO\(_4\)\(^3-\) antisymmetric stretching modes. The Raman bands at 1266, 1334 and 1368 cm\(^{-1}\) are assigned to AlOH deformation modes. The infrared band at 967 cm\(^{-1}\) is ascribed to the \(\nu_1\) PO\(_4\)\(^3-\) symmetric stretching vibrational mode. The infrared bands at 1024, 1072, 1089 and 1126 cm\(^{-1}\) are assigned to AlOH deformation modes. The infrared band at 967 cm\(^{-1}\) is ascribed to the \(\nu_1\) PO\(_4\)\(^3-\) symmetric stretching vibrational mode. The infrared bands at 1024, 1072, 1089 and 1126 cm\(^{-1}\) are attributed to the \(\nu_3\) PO\(_4\)\(^3-\) antisymmetric stretching vibrations. Raman bands at 553, 571 and 586 cm\(^{-1}\) are assigned to the \(\delta_{4\text{a}}\) out of plane bending modes of the PO\(_4\)\(^3-\) unit. Raman bands at 432, 457, 479 and 500 cm\(^{-1}\) are attributed to the \(\nu_3\) PO\(_4\)\(^3-\) and H\(_2\)PO\(_4\) bending modes. In the 2600 to 3800 cm\(^{-1}\) spectral range, Raman bands for whiteite are found 3426, 3496 and 3552 cm\(^{-1}\) are assigned to AlOH stretching vibrations. Broad infrared bands are also found at 3186 cm\(^{-1}\). Raman bands at 2939 and 3220 cm\(^{-1}\) are assigned to water stretching vibrations. Raman spectroscopy complimented with infrared spectroscopy has enabled aspects of the structure of whiteite to be ascertained and compared with that of other phosphate minerals.

**Introduction**

The mineral whiteite [1] is a phosphate mineral belonging to the jahnite mineral group [2]. In the whiteite formulae, the symbols in brackets indicate the dominant atom in three distinct structural positions, designated X, M(1), and M(2), in that order; for instance, magnesium Mg is always the dominant atom in the M(2) position for all the whiteite minerals [3]. For whiteite, the Al > Fe in the M3 position; if Fe > Al, then the mineral is jahnite. Moore and Ito (1978) [4] proposed that the whiteite group, which has the general formula XM(1)M(2)M(3)+-Jahnite-(CaMnMn)\(-(\text{PO}_4)^4(\text{OH})\)\(_4\)\(_r\)H\(_r\)O, is considered to consist of two series, with the M(3) site dominantly Al\(^3+\) for the whiteite series and Fe\(^3+\) for

\[\text{CaMn}^{++}\text{Mg}_2\text{Al}_2(\text{PO}_4)_4(\text{OH})_2-8(\text{H}_2\text{O})\]
the jahnsite series. The interesting chemistry of both whiteite and jahnite is these minerals contain multiple cations [5].

These two minerals form a continuous series of solid solutions [5]. Whiteite was named after John Sampson White Jr. (born 1933), associate curator of minerals at the Smithsonian Institution and founder, editor and publisher (1970–1982) of the Mineralogical Record. For example: whiteite-(CaFeMg), IMA1975-001, CaFe2+Mg2Al2(PO4)6(OH)2·8H2O; whiteite-(MnFeMg), IMA1978-A, Mn2+Fe2+Mg2Al2(PO4)6(OH)2·8H2O; whiteite-(CaMnMg), IMA1986-012, CaMn2+Mg2Al2(PO4)6(OH)2·8H2O; Rittmannite, Mn2+Mn2+Fe2+2Al2(PO4)6(OH)2·8H2O [4].

All members of the series belong to the monoclinic crystal system with point group 2/m. Most sources give the space group as P21/a for the Ca Fe rich member, which was the first of the series to be described, but Dana gives it as P2/a. The other members are variously described in different sources as having space groups P21/a, P2/a or Pa. Whiteite minerals occur as aggregates of tabular crystals, or thick tabular canoe-shaped crystals [3]. Whiteite from Rapid Creek in the Yukon Canada [1,2,6,7], is often associated with deep blue lazulite crystals. Whiteite is invariably twinned, giving the crystals a pseudo-orthorhombic appearance and the cleavage is good to perfect. The mineral is also located Iron Monarch mine, Iron Knob, Middleback Range, Eyre Peninsula, South Australia and from the Glen Wills mining district, Omeo, East Gippsland, Victoria, Australia.

Raman spectroscopy has proven very useful for the study of minerals [8–14]. Indeed, Raman spectroscopy has proven most useful for the study of diagnostically related minerals where isostructural substitution may occur as with wardite, cyrilovite and whiteite, as often occurs with minerals containing phosphate groups. This paper is a part of systematic studies of vibrational spectra of minerals of secondary origin. The objective of this research is to report the Raman and infrared spectra of whiteite and to relate the spectra to the molecular structure of the mineral.

Experimental

Samples description and preparation

The type locality for whiteite-(CaFeMg) and whiteite-(MnFeMg) is the Ilha claim, Taquaral, Itinga, Jequitinhonha valley, Minas Gerais, Brazil, and for whiteite-(CaMnMg) it is the Tip Top Mine (Tip Top pegmatite), Fourmile, Custer District, Custer County, Yukon, Yukon, USA [6]. For the Brazilian whiteite, it is found in association with eosphorite, zanazziite, wardite, albite, quartz.

The sample was incorporated to the collection of the Geology Department of the Federal University of Ouro Preto, Minas Gerais, Brazil, with sample code SAC-018. The sample was gently crushed and the associated minerals were removed under a stereomicroscope Leica MZ4. The whiteite sample was phase analyzed by X-ray diffraction. Scanning electron microscopy (SEM) in the EDS mode was applied to support the mineral characterization.

Wardite originated from Lavra Da Ilha, Minas Gerais, Brazil. Details of this mineral have been published (page 643) [15].

Raman spectroscopy

Crystals of whiteite were placed on a polished metal surface on the stage of an Olympus BHS microscope, which is equipped with 10×, 20×, and 50× objectives. The microscope is part of a Renishaw 1000 Raman microscope system, which also includes a monochromator, a filter system and a CCD detector (1024 pixels). The Raman spectra were excited by a Spectra-Physics model 127 He–Ne laser producing highly polarised light at 633 nm and collected at a nominal resolution of 2 cm⁻¹ and a precision of ±1 cm⁻¹ in the range between 200 and 4000 cm⁻¹. Repeated acquisitions on the crystals using the highest magnification (50×) were accumulated to improve the signal to noise ratio of the spectra. Spectra were calibrated using the 520.5 cm⁻¹ line of a silicon wafer. Previous studies by the authors provide more details of the experimental technique. Alignment of all crystals in a similar orientation has been attempted and achieved. However, differences in intensity may be observed due to minor differences in the crystal orientation.

Infrared spectroscopy

Infrared spectra were obtained using a Nicolet Nexus 870 FTIR spectrometer with a smart endurance single bounce diamond ATR cell. Spectra over the 4000–525 cm⁻¹ range were obtained by the co-addition of 128 scans with a resolution of 4 cm⁻¹ and a mirror velocity of 0.6329 cm/s. Spectra were co-added to improve the signal to noise ratio.

Spectral manipulation such as baseline correction/adjustment and smoothing were performed using the Spectracalc software package GRAMS (Galactic Industries Corporation, NH, USA). Band component analysis was undertaken using the Jandel ‘Peakfit’ software package that enabled the type of fitting function to be selected and allows specific parameters to be fixed or varied accordingly. Band fitting was done using a Lorentzian–Gaussian cross-product function with the minimum number of component bands used for the fitting process. The Gaussian–Lorentzian ratio was maintained at values greater than 0.7 and fitting was undertaken until reproducible results were obtained with squared correlations of r² greater than 0.995.

Results and discussion

Vibrational spectroscopy background

In aqueous systems, the Raman spectra of phosphate oxyanions show a symmetric stretching mode (ν₁) at 938 cm⁻¹, an antisymmetric stretching mode (ν₂) at 1017 cm⁻¹, a symmetric bending mode (ν₃) at 420 cm⁻¹ and a ν₄ bending mode at 567 cm⁻¹ [16–18]. S.D. Ross in Farmer [19] listed some well-known minerals containing phosphate which were either hydrated or hydroxylated or both [19]. However not all phosphate minerals were listed and there is a lack of information on anhydrous minerals. The vibrational spectrum of the dihydrogen phosphate anion has been reported by Farmer [19]. The PO₄ symmetric stretching mode occurs at 1072 cm⁻¹ and the POH symmetric stretching mode at ~878 cm⁻¹. The POH antisymmetric stretching mode was found at 947 cm⁻¹ and the POH bending mode at 380 cm⁻¹. The band at 1150 cm⁻¹ was assigned to the PO₂ antisymmetric stretching mode. The position of these bands will shift according to the crystal structure of the mineral.

The vibrational spectra of phosphate minerals have been published by Farmer’s treatise Chapter 17 [19]. The Table 17.III in Ref. [19] reports the band positions of a wide range of phosphates and arsenates, among other oxyanion minerals. The band positions for the monohydrogen phosphate anion of disodium hydrogen phosphate dihydrate is given as ν₁ at 820 and 866 cm⁻¹, ν₂ at around 460 cm⁻¹, ν₃ at 953, 993, 1055, 1070, 1120 and 1135 cm⁻¹, ν₄ at 520, 539, 558, 575 cm⁻¹. The POH unit has vibrations associated with the OH specie. The stretching vibration of the POH units was tabulated as 2430 and 2870 cm⁻¹, and bending modes at 766 and 1256 cm⁻¹. Water stretching vibrations were found at 3050 and 3350 cm⁻¹. The position of the bands for the disodium hydrogen phosphate is very dependent on the waters
of hydration. There have been several Raman spectroscopic studies of the monosodium dihydrogen phosphate chemicals [20–24].

Vibrational spectroscopy

The Raman spectrum of whiteite in the 100–4000 cm\(^{-1}\) spectral range is illustrated in Fig. 1a. This Raman spectrum shows the position of the Raman bands and their relative intensities. It is obvious that there are large parts of the spectrum where little or no intensity is observed. Therefore, the spectrum is subdivided into sections according to the type of vibration being investigated. In this way, the precise position of the bands can be detailed. The infrared spectrum of whiteite in the 500–4000 cm\(^{-1}\) spectral range is shown in Fig. 1b. The reflectance spectrum starts at \(\sim 500\) cm\(^{-1}\) because the ATR cell absorbs all infrared radiation below this wavenumber. As for the Raman spectrum, the infrared spectrum is subdivided into sections depending upon the type of vibration being examined. The complete infrared spectrum displays the position of the infrared bands and their relative intensity. It is noted that there is significant intensity in the hydroxyl stretching region in both the Raman and infrared spectra.

The Raman spectrum of whiteite over the 900–1500 cm\(^{-1}\) spectral range is illustrated in Fig. 2a. This spectral region is the region where the phosphate stretching modes are to be found. The spectrum is dominated by an intense sharp band at 972 cm\(^{-1}\). This band is assigned to the PO\(_4\)\(^{3-}\) \(\nu_1\) symmetric stretching vibration [8–12]. A low intensity shoulder band on the low wavenumber side of this band at 960 cm\(^{-1}\) is also found. A series of low intensity Raman bands at 1076 and 1173 cm\(^{-1}\) [8–14]. These bands are assigned to the PO\(_4\)\(^{3-}\) \(\nu_3\) antisymmetric stretching vibration. The Raman bands at 1266, 1334 and 1368 cm\(^{-1}\) are assigned to AlOH deformation modes [25]. The number of antisymmetric stretching modes provides evidence of reduced symmetry of the phosphate anion in the whiteite structure [8–12].

A comparison may be made with the spectroscopy of other phosphate minerals [8–14]. The Raman spectrum of wardite is dominated by two intense bands at around 995 and 1051 cm\(^{-1}\). These two bands are assigned to the PO\(_4\)\(^{3-}\) \(\nu_1\) symmetric stretching vibrations. Two intense bands are observed reflecting two non-equivalent phosphate units in the wardite structure. Breitinger et al. used FT-Raman to obtain their spectrum and found overlapping Raman bands at 999 and 1033 cm\(^{-1}\) and assigned these bands to the \(\nu_1\) PO\(_4\)\(^{3-}\) symmetric stretching and \(\nu_3\) PO\(_4\)\(^{3-}\) antisymmetric stretching modes. The difference in the spectra between our work and that of Breitinger et al., may be attributed to the improved technology of the spectrometer with greater resolution. Breitinger et al. also assigned the band at 999 cm\(^{-1}\) to AlOH deformation modes. In our work the Raman band at 995 cm\(^{-1}\) is very sharp and well resolved. The band at 1051 cm\(^{-1}\) is ever so slightly asymmetric on the low wavenumber side and a component may be resolved at 1045 cm\(^{-1}\). A group of low intensity bands are observed at 1083, 1109, 1140 and 1186 cm\(^{-1}\) and are assigned to the \(\nu_3\) PO\(_4\)\(^{3-}\) antisymmetric stretching modes. Breitinger et al. did not report any bands in these positions in the Raman spectrum.

The infrared spectrum over the 600–1300 cm\(^{-1}\) spectral range is provided in Fig. 2b. The infrared spectrum is broad; however
some spectral features are observed which may be resolved into component bands as is illustrated in this figure. The band at 967 cm\(^{-1}\) is ascribed to the PO\(_4\)\(^{3-}\) \(v_1\) symmetric stretching vibrational mode \([8–10]\). The infrared bands at 1024, 1072, 1089 and 1126 cm\(^{-1}\) are attributed to the PO\(_4\)\(^{3-}\) \(v_3\) antisymmetric stretching vibrations \([8–14]\). The infrared bands at 922 and possibly the 708 cm\(^{-1}\) band are attributed to water librational modes. The infrared spectrum of wardite shows a great deal more complexity when compared with the Raman spectrum.

The infrared band at around 994 cm\(^{-1}\) is attributed to the \(v_1\) PO\(_4\)\(^{3-}\) symmetric stretching mode. The cluster of bands at 1042, 1053, 1085, 1102, 1135 and 1165 cm\(^{-1}\) are attributed to the \(v_3\) PO\(_4\)\(^{3-}\) antisymmetric stretching modes. Some of these bands may also be due to the \(\delta(\text{Al}_2\text{O}_4)\) deformation modes, in harmony with the assignment of Breitinger et al. Breitinger and co-workers stated that the deceptively simple strong IR band centered at 1059 cm\(^{-1}\) contains at least four components of \(\nu(\text{PO}_4)\) generated by lifting of the originally threefold degeneracy of \(\nu(\text{PO}_4)\) and activation of \(v_1(\text{PO}_4)\) due to the general position of PO\(_4\) and again at least four components of the deformation modes \(\delta(\text{Al}_2\text{O}_4)\) involving the two pairs of the non-equivalent OH groups. In this work we have obtained much greater resolution and these components are resolved into the component bands.

The Raman spectrum of whiteite over the 300–700 cm\(^{-1}\) and 100–300 cm\(^{-1}\) spectral ranges are reported in Fig. 3. The spectrum in Fig. 3a may be subdivided into sections. (a) the bands at around 586 cm\(^{-1}\) (b) the bands in the 432–500 cm\(^{-1}\) spectral range and (c) bands below 400 cm\(^{-1}\). In addition, there is a low intensity band at 630 cm\(^{-1}\). The Raman bands observed at 553, 571 and 586 cm\(^{-1}\) are assigned to the \(v_4\) out of plane bending modes of the PO\(_4\) and possibly H\(_2\)PO\(_4\) units. The Raman spectrum of NaH\(_2\)PO\(_4\) shows bands at 526, 546 and 618 cm\(^{-1}\). The observation of multiple bands in this spectral region supports the concept of symmetry reduction of the phosphate. Intense Raman bands of wardite are observed at 588 and 620 with an additional band at 559 cm\(^{-1}\) are assigned to the \(v_4\) out of plane bending modes of the PO\(_4\)\(^{3-}\) and HOPO\(_2\)\(^{3-}\) units. Breitinger et al. assigned these bands to \(\nu(\text{Al}(\text{OH})_6)\) stretching vibrations. No phosphate bending modes in the work of Breitinger et al. were reported. The Raman spectrum of crystalline NaH\(_2\)PO\(_4\) shows Raman bands at 526, 546 and 618 cm\(^{-1}\) (data obtained by the authors).

Raman bands at 432, 457, 479 and 500 cm\(^{-1}\) are attributed to the \(v_2\) PO\(_4\) and H\(_2\)PO\(_4\) bending modes. The Raman spectrum of NaH\(_2\)PO\(_4\) shows two Raman bands at 460 and 482 cm\(^{-1}\). The observation of multiple Raman bands in this spectral region for the whiteite mineral supports the concept of symmetry reduction of the phosphate anion. A series of Raman bands for wardite are observed at 396, 416, 444, 464, and 489 cm\(^{-1}\). These bands are attributed to the \(v_2\) PO\(_4\)\(^{3-}\) and H\(_2\)PO\(_4\) bending modes. The Raman spectrum of NaH\(_2\)PO\(_4\) shows Raman bands at 460 and 482 cm\(^{-1}\). Thus, the series of Raman bands for wardite at 391, 401, 458, 485 and 510 cm\(^{-1}\) are attributed to the \(v_2\) PO\(_4\)\(^{3-}\) bending modes. Raman bands at 317, 446 and 515 cm\(^{-1}\) reported by Breitinger et al. were assigned to vibrational modes of the Al\(_2\)OH\(_6\) units. In the infrared spectrum of wardite, a series of infrared bands are observed at 620, 643 and 673 cm\(^{-1}\). These bands are attributed to the \(v_4\) out of plane bending modes of the PO\(_4\)\(^{3-}\) units. Breitinger et al. assigned bands in this region to \(\nu(\text{Al}(\text{OH})_6)\) stretching vibrations. In harmony with Breitinger et al. assignments, the infrared bands observed at 732, 795 and 893 cm\(^{-1}\) are attributed to water librational modes. Infrared bands observed at 573, 578 and 587 cm\(^{-1}\) are attributed to \(\gamma(\text{Al}(\text{OH}))\) vibrations.

Strong Raman bands are observed at 303 and 363 cm\(^{-1}\) with shoulder bands at 282 and 238 cm\(^{-1}\). These bands are assigned to

---

**Fig. 3.** (a) Raman spectrum of whiteite over the 300–700 cm\(^{-1}\) range (b) Raman spectrum of whiteite over the 100–300 cm\(^{-1}\) range.

**Fig. 4.** (a) Raman spectrum of whiteite over the 2700–3800 cm\(^{-1}\) spectral range (b) Infrared spectrum of whiteite over the 2500–3800 cm\(^{-1}\) range.
metal–oxygen stretching vibrations. Again, the observation of multiple bands in this spectral region supports the concept of the non-equivalence of phosphate units in the structure of whiteite. There are a number of bands in the Raman spectrum of the far low wavenumber region (Fig. 5b). These bands are ascribed to lattice vibrations. Intense Raman bands for wardite observed at 258 cm⁻¹ and 299 cm⁻¹ are related to the O–Al–O skeletal stretching vibrations. The intense band in all the spectra at 176 cm⁻¹ is considered to be due to H–OH hydrogen bonds. Other intense low wavenumber bands are observed for whiteite at 109 and 150 cm⁻¹.

The Raman spectrum of whiteite over the 2700–3800 cm⁻¹ spectral range is given in Fig. 4a. The infrared spectrum of whiteite over the 2500–3800 cm⁻¹ spectral range is given in Fig. 4b. There are two features of the Raman spectrum in this spectral region: (a) the very broad feature centred upon around 3220 cm⁻¹ and (b) the sharp bands at around 3496 cm⁻¹. The three bands at 3426, 3496 and 3552 cm⁻¹ are assigned to AlOH/AlF stretching vibrations. The broad feature may be resolved into component bands at 2939 and 3220 cm⁻¹ and these bands are assigned to water stretching vibrations.

The infrared spectrum shows a band at 3421 cm⁻¹ which may be assigned to the OH stretching vibration. As with the Raman spectrum, the broad feature centred around 3186 cm⁻¹ may be resolved into component bands at 3186 and 3360 cm⁻¹. These bands are assigned to water stretching vibrations. The infrared spectrum of wardite mineral samples display infrared bands at 3545 and 3611 cm⁻¹ and are attributed to AlOH stretching vibrations. The broad feature in the infrared spectrum at 3186 cm⁻¹ gives an indication that water is very strongly hydrogen bonded in the wardite structure.

The Raman spectrum of whiteite in the 1500–1800 cm⁻¹ spectral range is reported in Fig. 5a. The infrared spectrum of whiteite in the 1300–1800 cm⁻¹ spectral range is reported in Fig. 5b. The Raman spectrum displays an intensity Raman band at 1607 cm⁻¹ which is assigned to the water bending mode. This band is also observed in the infrared spectrum at 1626 cm⁻¹. This band is indicative of very weakly hydrogen bonded water. The infrared band at 1682 cm⁻¹ together with the Raman band at 1692 cm⁻¹ are attributed to more strongly hydrogen bonded water. The infrared bands at 1440 and 1577 cm⁻¹ may be an overtone or combination band.

Conclusions

Whiteite is a hydrated hydroxyl multi cation phosphate of magnesium and aluminum CaMn⁷⁺Mg₂Al₃[(PO₄)₆(OH)₂]·8(H₂O). The mineral is chemically related to wardite.

Raman spectroscopy complemented with infrared spectroscopy has been used to study aspects of the molecular structure of this phosphate mineral whiteite. The structure of whiteite is monoclinic. As a consequence multiple phosphate vibrational modes are observed. Raman and infrared bands are observed and attributed to phosphate, hydroxyl and water vibrational stretching and bending modes. The structure of wardite contains layers of corner-linked –OH bridged MO₆ octahedra stacked along the tetragonal C-axis in a four-layer sequence and linked by PO₄ groups. As a consequence at the molecular level non-equivalent phosphate units exist in the structure of whiteite. As a consequence multiple phosphate vibrational modes are observed.
