Introduction: Post-sepsis cognitive impairment is one of the major sequelae observed in survivors of sepsis. This cognitive impairment can be global or may affect specific domains. A better understanding of these deficits and associated risk factors could influence the care of patients with sepsis.

Objective: To perform a systematic review to investigate the presence of cognitive impairment and its associated risk factors among patients who survived sepsis.

Methods: The search was conducted in MEDLINE (1966 to March 2017) and EMBASE (1988 to March 2017). We included studies with individuals who were 18 years or older with post-sepsis cognitive impairment. Results: We analysed 577 articles. Sixteen studies met the inclusion criteria. More than 74,000,000 patients were evaluated in the selected studies. Significant variation was observed in the definition of sepsis and cognitive impairment. Twelve studies used ACCP/SCCM criteria for sepsis, while cognitive impairment was defined per test used. Post-sepsis cognitive impairment was observed in 12.5 to 21% of survivors of sepsis. Attention, cognitive flexibility, processing speed, associative learning, visual perception, work memory, verbal memory, and semantic memory were the specific domains affected. Depressive symptoms, central nervous system infection, length of hospitalisation due to infection, and temporal proximity to the last period of infection were associated with cognitive impairment.

Conclusion: The studies are heterogeneous, and there is urgent need for a common language, including definitions and neuropsychological tests, for the investigation of post-sepsis cognitive impairment. Despite this, there is mounting evidence for the clinical relevance of post-sepsis cognitive impairment.

1. \textbf{Introduction}

Sepsis is a systemic inflammatory response of the host to a pathogenic microorganism. Sepsis is a major health problem, with data demonstrating an increase in incidence rate\textsuperscript{1-4} and mortality in certain groups.\textsuperscript{5} A recent global study showed that one third of patients with sepsis die before leaving the hospital.\textsuperscript{6} Furthermore, according to the Global Sepsis Alliance, at least 20% of survivors of sepsis have some form of sequelae,\textsuperscript{7} such as physical or cognitive impairment, mood disorders, and poor quality of life.\textsuperscript{8}

Cognitive dysfunction in patients who survive sepsis can be characterized by new deficits (or exacerbations of preexisting mild deficits) in global cognition or executive function.\textsuperscript{9} Septic associated encephalopathy (SAE) may be defined as a cognitive dysfunction associated with sepsis, without the presence of infection, in the central nervous system (CNS) or structural brain injury after excluding metabolic causes. SAE may be acute, subacute, or chronic. SAE manifested only during the course of the disease with improvement after its control can be classified as acute.\textsuperscript{10} Symptoms that...
last weeks to months can be considered subacute, while symptoms that persist over a year are categorized as chronic. Subacute and chronic deficits elicit substantial interest as affected individuals may require rehabilitation or home care.

Recently, there has been a progressive increase of studies evaluating cognitive changes associated with sepsis. Due to the potential negative impact of such amendments, there is great interest from the scientific community, health managers, and patients’ families on the subject. Conducting a systematic review on the topic could summarize the studies carried out so far, provide the reader with the best available evidence, and indicate the gaps that still exist. We conducted a systematic review to determine cognitive impairment and its associated risk factors among patients who survived sepsis.

2. Methods

2.1. Types of participants

Individuals who were 18 years or older with post-sepsis cognitive impairment were included in this study. Post-sepsis refers to any time after the diagnosis of sepsis. Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection. Patients with human immunodeficiency virus (HIV) infection were excluded as immunosuppression and use of antiretroviral drugs could have influenced the course of sepsis and cognition of these individuals. Individuals under 18 were also excluded due to neurodevelopmental features that must be taken into consideration when studying children and adolescents.

2.2. Study selection criteria

Publications selected for review were case-control, cohort, and clinical trials studies written in English, Spanish, or Portuguese. To be included, studies needed to have assessed the association between cognitive dysfunction and sepsis and/or at least one potential risk factor for the occurrence of SAE. There was no restriction regarding date of publication and time of follow-up of each study.

Studies that reported subjective measures of cognitive outcome, such as the opinions of the staff regarding the cognitive state of patients were excluded. Single case reports, unpublished studies, scientific meeting abstracts, review studies, comments and letters to the editor were excluded.

2.3. Outcome measures

The primary outcome measure for this review was the cognitive performance of post-sepsis individuals as measured by cognitive tests, scales, or batteries such as, but not limited to, the Wechsler Adult Intelligence Scale, Boston Naming Test, Wechsler Memory Scale, Trail Making Test (TMT), Informant Questionnaire on Cognitive Decline in the Elderly, and Mini-Mental State Examination.

2.4. Search strategy

The search was conducted in the databases MEDLINE (1966–present) and EMBASE (1988–present) (see Appendix A, Supplementary data). The search was first conducted on May 10th, 2015, and was updated on October 17th, 2015, and on March 20th, 2017. The information that could not be extracted by reading the articles was requested by e-mail from the corresponding author.

2.5. Study selection

Two investigators independently reviewed the search results to identify relevant studies. Disagreements were resolved by consensus, and if necessary a third investigator was consulted. First, studies were excluded based on the title; titles that were not related to the subject sepsis or cognition were excluded. In the next stage, studies were evaluated by reading the abstracts; studies that did not examine cognition in the context of sepsis were excluded. After reading the abstracts, selected studies were thoroughly read; at this last stage, studies that met all the eligibility criteria described above were included in the review. The Newcastle-Ottawa form assigns a maximum of four points for selection, two points for comparability and three points for exposure or outcome. In the current study, we considered a study awarded seven or more points as a high-quality study.

2.6. Data extraction process and literature quality assessment

We developed a data extraction table based on the Cochrane template. One investigator (A.J.C.C) extracted the data and a second (A.L.T.) verified the extracted data. In addition, two investigators (A.J.C.C. and A.L.T.) independently cross-checked the risk of bias using the Newcastle-Ottawa Scale for observational studies. Any disagreement between investigators was resolved by consensus, and if necessary a third investigator (V.N.) was consulted.

2.7. Data items

The following information was taken from each selected study: (1) country where the study was conducted, (2) type of study, (3) follow-up period, (4) sample size, (5) characteristics of the study population (mean age, sex, eligibility criteria, classifications used, and data collection location), (6) primary and secondary outcome, (7) cognitive outcome evaluated, and (8) main results of the study. Other data such as (1) the definition of sepsis used, (2) definition of cognitive impairment used, (3) cognitive impairment associated with sepsis found, and (4) risk factors associated with post-sepsis cognitive impairment were also extracted.

In general, studies that have not incorporated multivariate techniques to identify risk factors have little value. For the purposes of this synthesis, only variables for which at least one study reported either a risk ratio (RR) or odds ratio (OR) (regardless of statistical significance reported) or a statistically significant association (regardless of the OR/RR reported) were considered.

3. Results

3.1. Description of studies

The search results are presented in Fig. 1. Five hundred seventy-seven potentially relevant articles were identified. After exclusion of 57 duplicate studies, by judging the title and abstract, 490 articles were excluded, as they did not meet the inclusion criteria. Thirty articles were retained for in-depth inspection. Sixteen articles were retained for this systematic review. There was 100% agreement between reviewers in the selection of articles that met the inclusion criteria of the study.

3.2. Characteristics of included studies

The sixteen selected studies comprised six prospective cohort with control group, six prospective cohort without control group, three retrospective cohort without control group, and one case-control study. No clinical trials met the inclusion criteria.

The sixteen studies included 74,313,495 patients in total, with the majority of patients from Iwashyna et al., while the remaining studies contributed with 193,907 patients. The average age of the subjects included in the studies showed wide variation in range from 19 to 81 years. In most studies the mean age of patients was over 60 years (Table 1).

</table>
While considering formal education data, only four studies indicated the average level of education of patients. Two studies indicated the average schooling of their patients as 7.9 and 12.6 years. The others referred to the patients' education level by categorizing them into having graduated or not from Secondary education and having graduated or not from Higher education (Table 1).

The quality of the studies was assessed with the Newcastle-Ottawa Score and the results are presented in Tables 2 and 3. Four studies were classified as high quality. The mean value for the sixteen studies assessed was 5.3 indicating a low overall quality.

3.3. Definition of sepsis, severe sepsis, and septic shock

There was variation in the definition of sepsis, severe sepsis, and septic shock among the selected studies. The majority of studies used as reference the criteria of the American College of Chest Physicians/Society of Critical Care Medicine (ACCP/SCCM), Others used the International Statistical Classification of Diseases (ICD-8 and/or ICD-10). No reference was made to the definition of sepsis by Lahariya et al., Arinzon et al., and Pierrakos et al.

3.4. Definition of cognitive impairment patients

The definition of cognitive impairment patients showed great variation among the selected studies. Iwashyna et al. and Davydow et al. used the “Telephone Interview for Cognitive Status (TICS)” test to categorize patients into mild to moderate or severe cognitive impairment, the cutoff points used were based on previous studies. Other studies used the Informant Questionnaire on Cognitive Scale Decline in the Elderly (IQCODE) with predefined cutoffs to classify patients into moderate to severe cognitive impairment or suspected dementia.
A diagnosis of cognitive impairment was made by Merli et al.\textsuperscript{16} with the Trail Making Test A, B or a Digit-Symbol Test Z-score\textsuperscript{33} greater than two standard deviations from the mean of a healthy Italian population, adjusted for age and education.\textsuperscript{34}

Semmler et al.\textsuperscript{17} calculated a composite Z-score for cognition using the NeuroCogFX, Trail-making Tests A and B and Multiple Choice Word Test-B. The score considered the results of applied cognitive tests after sepsis (NeuroCogFX and Trail-making Tests A and B), and Multiple Choice Word Test-B German vocabulary test, which aim is to quantify the patients’ premorbidity cognitive status. A Z-score between −1.5 and −2.0 was considered denoting mild cognitive impairment.

Other strategies to define cognitive impairment were the use of the “Confusion Assessment Method in the Intensive Care Unit” (CAM-ICU),\textsuperscript{19,23-26} an MMSE score less than 24,\textsuperscript{26} Glasgow Coma Score <8 despite resolution of sepsis after exclusion of any underlying pathology that could explain this state,\textsuperscript{26} abnormal Clock Drawing Test,\textsuperscript{26} or searching predetermined International Classification of Diseases (ICD-9-CM) codes\textsuperscript{25} in databases.\textsuperscript{28}

Although most studies did not state this, all tools described in this section to assess cognitive impairment had been previously validated.\textsuperscript{36-42} The neuropsychological outcomes reported by each author were assessed and are presented in Table 5.

Some studies did not explain their categorization methods or cutoff points used to define cognitive impairment.\textsuperscript{19,20,22,28,30}

### 3.5. Post-sepsis global cognitive impairment

Analysing the selected studies in this review, we found that Iwashyna et al.\textsuperscript{27} showed moderate to severe cognitive impairment after 3 years in 16.7% (95% CI: 12.3, 21.0%) of patients who survived sepsis. The same author had found an odds ratio (OR) of 3.34 for moderate to severe cognitive impairment after sepsis in a study published two years earlier.\textsuperscript{8} In a study by Davydow et al.,\textsuperscript{21} cognitive impairment ranged from 14 to 20%, with 60% of individuals being classified as moderately to severely impaired. It was also shown by Benros et al.\textsuperscript{29} that hospital contact due to any infectious condition worsened global cognitive performance, assessed by a Danish Intelligence Test by 76% (95% confidence interval, 61–92%), sepsis was associated with a mean score of 1.60-units lower cognitive ability.

### 3.6. Post-sepsis specific cognitive domains impairment

Some studies have reported cognitive changes in specific domains. Visual search, perceptual/motor speed, speed of processing, working memory, and general intelligence are among the most frequently cited constructs thought to contribute to Trail Making Test performance.\textsuperscript{43} Merli et al.\textsuperscript{16} showed that median Z-scores for Trail Making Test-A were significantly lower in patients with sepsis when compared to patients without infection. Associative learning,

a NeuroCogFx (Digit Span, 2-back-test, alertness, go-no-go, interference, verbal memory, figural memory, phonetic verbal fluency).
b A Danish intelligence test.
c A screening instrument for dementia and mild cognitive impairments.
processing speed, visual perception, and working memory assessed by the Digit Symbol Test was also lower in patients with sepsis. 16

Semmler et al. 17 found long term mild cognitive impairments in attention, verbal fluency, executive function, and verbal memory in survivors of sepsis when compared to their previously estimated intelligence level.

A long-term visual processing impairment in patients with sepsis post-infection was observed by Götz et al. with magnetoencephalographic measurements. 20

3.7. Associations between sepsis and cognition

Most studies assessed the association between cognitive impairment and sepsis (Table 4). 8,16,17,21,27,29,30 Some studies showed that sepsis is a risk factor for worsening cognitive performance after ICU discharge 28 or demonstrated an association between sepsis and delirium, a clinical syndrome that encompasses several cognitive changes. 18,23–25

The presence of pre-sepsis depressive symptoms was considered a risk factor for post-sepsis cognitive impairment. 21 Infection in the CNS, number of hospital visits due to infection, length of hospitalization due to infection, family history of infection, and temporal proximity to the latest episode of infection were identified as risk factors for cognitive impairment observed after infectious conditions. 29 Critical illness in the presence of infection, especially severe sepsis, was identified as one of the risk factors for the subsequent diagnosis of dementia within three years of hospital discharge. 28

Sepsis was a risk factor for the development 29 and longer duration 28 of delirium. Moreover, Arinzon et al. 24 showed that a diagnosis of sepsis increased the mortality rate in patients with delirium.

Several risk factors were evaluated in the included studies, but many did not affect the outcome evaluated (Table 4). For instance, it was found that cognitive deficits related to sepsis were not influenced by the length of stay in the ICU, ICU discharge time, number of days on mechanical ventilation, APACHE II, and SOFA scores. 17 The patient’s age, family history of psychiatric illness, and substance abuse similarly did not affect cognitive performance after infection. 29

3.8. Workup on sepsis associated encephalopathy

The diagnosis of sepsis-associated cognitive dysfunction was additionally evaluated by the selected studies. 17,24,25

An association between SAE and electroencephalography (EEG) parameters was observed; as the occurrence of cognitive impairment in the days after EEG recording was associated with previous EEG findings, such as delta frequency dominant EEG, absence of EEG reactivity, Synk grade ≥3 (an EEG classification with prognostic value for comatose patient that range from 0 to 5), and Young grade ≥1 (an EEG classification for septic encephalopathy that ranges from 0 to 4). 25

The diagnosis of SAE with the pulsatility index, an indicator of cerebrovascular resistance, measured by transcranial Doppler was evaluated. A pulsatility index greater than 1.3 at 24-h post sepsis diagnosis correlated with SAE (OR: 5.66, 95% confidence interval: 1.1–29.11). 24 Although no correlation between cognitive dysfunction after sepsis and pulsatility index was found, when multivariate analysis was performed in another study by the same author. 26

Magnetoeencephalographic (MEG) techniques were used to study the long-term brain electrophysiology changes after sepsis. Combining MEG data with neuropsychological tests, suggested abnormal thalamocortical dynamics 19 and a disruption in neural networking, especially complex networking, in patients with long-term post-sepsis. 20

Computerized volumetric techniques of magnetic resonance images showed significant differences in left and total hippocampal volumes between patients with sepsis and healthy controls. The hippocampal volume in patients without sepsis admitted in the ICU was between that of patients with sepsis and healthy controls. A correlation analysis between cognitive performance and hippocampal volume was not performed. 17

4. Discussion

To the best of our knowledge, this is the first systematic review to identify and synthesize the best available evidence on post-sepsis cognitive impairment. The analysed studies showed that sepsis can worsen cognitive performance in the short, medium, and long terms. The available studies did not provide robust evidence to determine the risk factors that modulate the association between sepsis and cognitive impairment. Regarding the great heterogeneity in the definition of cognitive impairment and the use of several cognitive tests, the comparison among studies was impaired.

The use of batteries and tests evaluating global cognitive function was most frequently employed. This strategy is in line with the theory that sepsis causes wide brain function alterations. The cognitive test batteries Telephone Interview for Cognitive Status (m-TICS), 3,21,27 NeuroCogFx, 11 MMSE, 16,22,23,26 Clock Drawing Test, 26 Adult Neuropsychological History form, 20 Burke-Priens test, 29 IQCODE, 18,27 and DemTect 19,20 were used for global cognitive assessment. Some tests as the Symbol–Digit test, 16 Trail Making Test A and B, 16,17 Rey Complex Figure Test 12 provided more specific information about cognitive domains. Only one study, by Semmler et al., 17 showed changes in certain cognitive domains, such as attention, verbal fluency, executive function, and verbal memory. Semmler et al. 17 proposed that an asymmetric distribution of neurotransmitters in the human brain would lead to increased vulnerability of the left hemisphere to inflammatory insults.

In a cohort study performed with patients with critical illness by Pandharipande et al. 9 the cognitive sequelae ranged between 24 to 40% depending on the timing of cognitive evaluation. This study used the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) that was not used in the studies included in this review. As shown, our analysis suggests that equally important to timing is the choice of testing means, for cognitive evaluation. To compare the incidence and prevalence of cognitive dysfunction between patients with sepsis and patients with other diseases it is necessary to achieve a consensus on the appropriated test to be used, beforehand.

Most of the evaluated studies were conducted with patients over the age of 60 years. 3,18,21–28 Despite sepsis increased incidence and mortality in the elderly compared to younger patients, 26 it is important to evaluate the impact of sepsis on young individuals who are still part of the workforce. Whereas cognitive reserve has been identified as a protective factor for cognitive impairment in several studies, 47–49 the possibility of young patients exhibiting less post sepsis deficits could be explained at least in part by their higher cognitive reserve.

Differences were observed in the criteria used to classify patients with sepsis. In some cases, they were classified by combinations of disease codes, and in others through the direct analysis of clinical history and laboratory data. Disagreements regarding diagnosis of sepsis depended on the purpose of the study. Studies that focus on sepsis diagnosis in individuals, usually have therapeutic and/or prognostic implications; therefore, these need to be more pragmatic and their diagnostic criteria should be easily applicable. In contrast, an epidemiological definition, often used in clinical trials, would need to be rigorous and robust. 5 In 2015, the Sepsis-3 guideline, a new clinical criteria for sepsis and septic shock was...
developed, and, for the first time, the recommended primary ICD-9 and ICD-10 codes and a framework for implementation for coding and research in an attempt to facilitate research and increase accuracy of coding.\textsuperscript{11,12}

The criteria used to classify individuals as presenting with cognitive impairment also differed among studies, even when using the same cognitive tests. The choice of cut-offs depends on the authors’ choice between higher specificity and higher sensitivity. When the goal is to identify individuals with cognitive impairment, tests with greater sensitivity are preferred, but when the objective is to determine the exact nature of the patient’s deficit, specific tests are preferable. A method to compare the performance of tests that measure different cognitive abilities is through standardized scores, such as the Z-score. Only two studies reported cognitive data through standardized scores,\textsuperscript{16,17} their scarce use may be due to lack of good quality standardized data or even lack of sufficient data in the studied population, especially among ethnic minorities.\textsuperscript{50}

We did not locate studies with a design that robustly assessed the risk factors associated with the development of post-sepsis cognitive impairment. Factors such as pre-sepsis depressive symptoms, infection in the CNS, length of stay, and temporal proximity to the latest episode of infection seem to be involved in cognitive impairment associated with sepsis. Studies with patients post-ICU hospitalization have suggested the influence of some factors on cognition, such as sedatives and analgesics,\textsuperscript{51} antipsychotics,\textsuperscript{53} antibiotics,\textsuperscript{56} glycemic control,\textsuperscript{57} corticosteroids,\textsuperscript{58} and cognitive reserve.\textsuperscript{59} The influence of these factors must be better investigated in future studies.

In a study published by Larson et al.,\textsuperscript{56} cognitive reserve associated with the magnitude of cognitive impairment in patients with acute respiratory distress syndrome. In this systematic review, the issue was not explored. In the study of Semmler et al.,\textsuperscript{63} although the author estimated cognitive reserve with neuropsychological testing, a correlational analysis between cognitive reserve and post-sepsis cognitive performance was not performed. Lahariya et al.\textsuperscript{53} used the IQCODE score to evaluate the pre-morbidity cognitive reserve in a sample, finding that patients with low cognitive reserve (i.e. IQCODE > 3.3) had an odds ratio of 10.81 for delirium.

Our study had a number of limitations. The search conducted did not involve a comprehensive list of search terms. The heterogeneity of the tests and cutoff points used in the studies analyzed did not provide the necessary data for performing a meta-analysis. There was no consensus among the authors regarding the best tests to evaluate post-sepsis cognitive changes. The limited number of available studies, the marked differences among the populations studied, and the diversity of outcomes complicated the generalisability of the study findings. The quality of the studies varied widely.

Our review revealed several gaps in the accumulated knowledge on post-sepsis cognitive impairment. We observed that there is need for studies to assess the most appropriate neuropsychological tests and to compare global cognitive assessment tests to domain specific tests (e.g. attention and memory). Furthermore, the assessment of post-sepsis cognitive impairment in subgroups of young and elderly patients could provide clues about the role of cognitive reserve on post-sepsis cognitive impairment. Studies with cognitive impairment biomarkers (e.g. neurotrophic, neurodegenerative, inflammatory, and oxidative stress biomarkers) and neuroimaging have also been perceived as missing or sparse.

In conclusion, this systematic review demonstrates that there is increasing evidence for the existence of post-sepsis cognitive impairment. Due to lack of consistent findings, the same cannot be stated about its associated risk factors.
